## ABSTRACT

We report the detection of the first extrasolar planet, ET-1 (HD 102195b), using the Exoplanet Tracker (ET), a new-generation Doppler instrument. The planet orbits HD 102195, a young star with solar metallicity that may be part of the local association. The planet imparts radial velocity variability to the star with a semiamplitude of  $63.4 \pm 2.0 \text{ m s}^{-1}$  and a period of 4.11 days. The planetary minimum mass ( $m \sin i$ ) is  $0.488 M_J \pm 0.015 M_J$ . The planet was initially detected in the spring of 2005 with the Kitt Peak National Observatory (KPNO) 0.9 m coudé feed telescope. The detection was confirmed by radial velocity observations with the ET at the KPNO 2.1 m telescope and also at the 9 m Hobby-Eberly Telescope (HET) with its High Resolution Spectrograph. This planetary discovery with a 0.9 m telescope around a  $V = 8.05$  magnitude star was made possible by the high throughput of the instrument: 49% measured from the fiber output to the detector. The ET's interferometer-based approach is an effective method for planet detection. In addition, the ET concept is adaptable to multiple-object Doppler observations or very high precision observations with a cross-dispersed echelle spectrograph to separate stellar fringes over a broad wavelength band. In addition to spectroscopic observations of HD 102195, we obtained brightness measurements with one of the automated photometric telescopes at Fairborn Observatory. Those observations reveal that HD 102195 is a spotted variable star with an amplitude of  $\sim 0.015$  mag and a  $12.3 \pm 0.3$  day period. This is consistent with spectroscopically observed Ca II H and K emission levels and line-broadening measurements but inconsistent with rotational modulation of surface activity as the cause of the radial velocity variability. Our photometric observations rule out transits of the planetary companion.

*Online material:* color figures

## 1. INTRODUCTION

Over the past 15 years, the field of extrasolar planets has moved from the fringes of science to become a central pillar of current and future astronomical studies. Although the first extrasolar plan-

ets were discovered by radio observations of a pulsar (Wolszczan & Frail 1992), the vast majority of the over 170 known extrasolar planets orbit main-sequence stars and were found using cross-dispersed echelle spectrographs at a dozen ground-based telescopes. The first detected extrasolar planet associated with a main-sequence star, 51 Peg (Mayor & Queloz 1995), ushered in a continuous stream of unexpected results on extrasolar planets, ranging from their extreme diversity (“hot Jupiters,” planets in very elongated orbits, multiple-Jupiter-mass planetary systems) to the recently discovered super-Earth-mass planets around solar

<sup>2</sup> Michelson Graduate Fellow.

type stars with orbital periods of a few days. A review of the field is given by Marcy et al. (2006). These discoveries not only provide new challenges for the fields of planetary origins and evolution but also indicate that a large sample of planets is required to obtain a full understanding of their nature.

Although the high-precision echelle Doppler instruments have proven quite successful at detecting extrasolar planets, the current approach is costly and time-consuming because of the large telescopes required and the relatively low throughputs (a few percent) of the spectrographs, as well as the limitation of observing one star at a time. A sample of approximately 5000 stars (generally the closest and brightest ones), including the 2000 N2K survey stars targeting for short-period planets (Fischer et al. 2005), has been monitored for planets with echelle instruments on a dozen telescopes, including most of the new-generation large telescopes such as Keck, the Very Large Telescope (VLT), Subaru, the Hobby-Eberly Telescope (HET), and Magellan. Most of the target stars have visual magnitudes brighter than about 8.0, except the N2K targets stars with visual magnitudes brighter than about 10.5 (Fischer et al. 2005). Based on the current planetary detection rate of  $\sim 7\%$  among solar type stars (Marcy et al. 2006), a few hundred planets will likely be detected over the next 10 years using current techniques. Given the surprising range of properties known to date (and the likelihood of even larger surprises in the future), this sample will still be inadequate for giving us a comprehensive picture of planet formation and evolution and their relation to stellar properties such as mass, luminosity, spectral type, metallicity, duplicity, and age. Furthermore, to monitor a large number of stars, one must move to targets with  $V > 8.0$ . An instrument with high throughput becomes critical to searching for planets around fainter stars. In addition, an instrument with multiple object capability would greatly enhance the efficiency of any extrasolar planet survey.

A promising Doppler technique for finding extrasolar planets, one that is quite different from the echelle approach, uses a dispersed fixed-delay interferometer (DFDI) for precision radial velocity (RV) measurements. The DFDI offers high throughput and multi-object capability. Instead of measuring the absorption-line centroid shifts in the echelle approach, a DFDI determines the radial velocity by monitoring interference fringe phase shifts. The idea for using a fixed-delay interferometer for high-precision Doppler measurements was first proposed by solar astrophysicists in the 1970s and 1980s to measure solar oscillations (Barker & Hollenbach 1972; Gorskii & Lebedev 1977; Beckers & Brown 1978; Kozhevnikov 1983). This approach was adopted by the Global Oscillations Network Group (GONG) interferometer (Harvey et al. 1995). The GONG interferometer, with a narrow passband ( $\sim 1 \text{ \AA}$ ), has produced very high Doppler precision measurements of the Sun (sub  $\text{m s}^{-1}$  precision for the GONG measurements; J. Harvey 2002, private communication). The concept of combining a fixed-delay interferometer with a moderate-resolution spectrometer for broadband operations for high-precision stellar Doppler measurements was proposed in 1997 by David Erskine at Lawrence Livermore National Laboratory. The initial lab experiments and telescope observations successfully demonstrated the DFDI concept (earlier this concept was called the fringing spectrometer and externally dispersed interferometer [EDI]; Erskine & Ge 2000; Ge et al. 2002). The theory for DFDI is described in Ge (2002). In 2002 a prototype DFDI instrument, designated as the Exoplanet Tracker (ET), was used at the KPNO 2.1 m telescope to reproduce the radial velocity curve of the known planet orbiting the solar type star 51 Peg (van Eyken et al. 2004a), demonstrating the capability of this new approach for planet detection. A new version of the ET instrument, optimized for high throughput and relatively large

wavelength coverage compared to the 2002 prototype, was commissioned at the KPNO 0.9 m coudé feed and 2.1 m telescopes in 2003 November (Ge et al. 2004; van Eyken et al. 2004b). The first DFDI multi-object observations, using a modified ET, were obtained in 2005 March at the 2.5 m Sloan Digital Sky Survey (SDSS) telescope (York et al. 2000; Gunn et al. 2006) at Apache Point Observatory (Ge et al. 2005).

In this paper, we report the first detection of a new extrasolar planet using the DFDI technique. The planet, HD 102195b (ET-1), associated with the star HD 102195, has an orbital period of 4.11 days and was discovered with ET at the KPNO 0.9 m coudé feed and 2.1 m telescopes. The planet survey instrumentation and observations are reviewed in § 2, and a description of the survey data processing is provided in § 3. Section 4 presents additional radial velocity, spectroscopic, and photometric observations of HD 102195. An analysis of the radial velocity curve and follow-up data of HD 102195 and a brief discussion of the properties of ET-1 are given in §§ 5 and 6, respectively.

## 2. EXOPLANET TRACKER: DESCRIPTION AND INITIAL SURVEY

In the winter of 2004 we began a small-scale extrasolar planet survey at KPNO using the DFDI approach. This program is designed to detect new planets with short orbital periods ( $< 10$  days). Targets were chosen primarily from the Nstar catalog (Gray et al. 2003), selecting dwarf stars of type FGK with  $7.8 < V < 9$ . Stars that were known to be fast rotators or had high-activity indicators were removed from the sample, as were any known visual doubles or variables. Since studies have shown a strong correlation between the frequency of planetary systems and high metallicity in the star (e.g., Gonzalez 1997; Reid 2002; Santos et al. 2004; Fischer & Valenti 2005), we selected relatively high metallicity stars ( $[M/H] > 0.0$ ) to increase the planet detection efficiency.

Below we present a brief outline of the exoplanet tracker, of which a more detailed description can be found in van Eyken et al. (2004b). ET includes a single object fiber feed system, a Michelson-type interferometer with a fixed optical delay in one of the arms, a spectrograph with a volume phase holographic (VPH) grating, and a  $4K \times 4K$  CCD camera with  $15 \text{ }\mu\text{m}$  pixels. An optical fiber with a  $200 \text{ }\mu\text{m}$  core diameter ( $2''.5$  on the sky) is fed by an  $f/8$  beam from the KPNO 0.9 m coudé feed or 2.1 m telescope (both telescopes are housed in the same enclosure and feed the same spectrograph, so the instrument does not have to be relocated). The fiber has an  $f/6$  output beam. ET is designed to operate from 5000 to  $5640 \text{ \AA}$  and has a spectral resolving power of  $\sim 5100$ . A resolution element is sampled by 6.7 pixels in the dispersion direction. Each fringe is sampled by  $\sim 58$  pixels in the slit direction; this range usually includes  $\sim 5$  periods of fringing. The VPH grating is a Dickson-type design, which produces a 92% peak grating efficiency but with a limited grating operation band of  $\sim 600 \text{ \AA}$ . The CCD camera was purchased from Spectral Instrument, Inc. The detector is a back-illuminated CCD with  $\sim 90\%$  quantum efficiency in the ET operating wavelengths.

The measured instrument throughput from the fiber output to the detector is 49%. The overall average detection efficiency, including the telescope, seeing, fiber, instrument, and detection losses is 18% under typical seeing conditions ( $\sim 1''.5$ ) at the KPNO coudé feed/2.1 m. An iodine vapor glass cell 150 mm long and 50 mm in diameter is used as a Doppler zero-velocity reference. The cell temperature is stabilized to  $60^\circ\text{C} \pm 0.1^\circ\text{C}$ . Since 2003, we have been able to recover the expected RV signatures of known planets routinely with the ET instrument (see Fig. 1) and have obtained short-term (2 day) precision as high as  $3.6 \text{ m s}^{-1}$  (photon noise-limited) on the bright RV stable star 36 UMa (van Eyken et al. 2004b). The

FIG. 1.—RV measurements of 51 Peg taken with ET at the 0.9 m coude feed in 2005 May. The solid line is the predicted RV curve based on the orbital solution in Marcy et al. (1997). The exposure times were 15 minutes, and the typical RV error for each point is  $7.9 \text{ m s}^{-1}$ .

instrument long-term precision has not been well characterized yet. The preliminary RV measurements over 2 months show that the instrument is at least stable to  $\sim 13 \text{ m s}^{-1}$ .

The initial ET planet survey of 90 stars without previous precision radial velocity observations was conducted during the period 2004 December–2005 May with the KPNO 0.9 m coude feed from December to March and the 2.1 m telescope in May. A total of 59 nights of the coude feed time and 7 nights of 2.1 m time were allocated to the program. Observations on 43 nights were obtained during the survey (losses were primarily due to poor weather).

The survey was divided into five observation blocks, each of  $\sim 10$  nights duration. Star and iodine templates were obtained at the beginning and end of each block (van Eyken et al. 2004a). For a typical block, 5–6 RV measurements were acquired for each survey star. The RV data were taken with the iodine vapor cell in the stellar beam. The instrument was set to the same configuration during each observation block to maximize the instrument stability. The interferometer fringe pattern was stabilized by a closed-loop, actively controlled piezoelectric transducer (PZT) system connected to one of the interferometer arms. The fringe pattern was monitored with a stabilized HeNe laser at  $0.6328 \mu\text{m}$  purchased from Melles Griot, Inc. To measure the illumination profile and the spectral line slant for each fringe while maximizing the instrument stability, the interferometer fringes were jittered at the beginning and the end of each observation block to produce nonfringe calibration data. The jitter of the interferometer fringes was produced by operating the interferometer PZT ramp generators at about 10 Hz. The interferometer phase was locked during the observations in each block. The instrument room was heated to  $\sim 24^\circ\text{C}$ , and the rms temperature fluctuation during the runs was approximately  $0.1^\circ\text{C}$ . The absolute velocity drift due to the temperature fluctuation and mechanical instability is about  $1\text{--}2 \text{ km s}^{-1}$ . This velocity drift is calibrated and corrected with the iodine absorption-line fringes.

Typical individual exposure times are  $\sim 25$  minutes for  $V \sim 8$  and  $\sim 40$  minutes for  $V \sim 9$  stars at the coude feed; typical exposure times for the 2.1 m are 10 minutes for all targets. The average rms RV precision (photon noise) is  $\sim 20 \text{ m s}^{-1}$  at the coude feed and  $\sim 17 \text{ m s}^{-1}$  at the 2.1 m. A total of  $\sim 650$  ET observations of 90 stars were obtained during this campaign.

### 3. SURVEY DATA PROCESSING

The data produced by ET required the development of a large software processing system. In this section we briefly outline the steps required to extract precision RV measurements from the raw data recorded by the detector. The main steps in the processing of the ET fringe spectra are (1) image preprocessing, (2) sinusoid fitting, and (3) RV shift determination.

*Preprocessing.*—Image preprocessing is performed with a combination of standard IRAF procedures<sup>3</sup> and proprietary software written in Research Systems Inc.'s IDL data analysis language. The steps consist of the following:

1. *Background subtraction/trimming.*—Detector bias and background light calibration images (dark plus stray light) are first subtracted from the raw data. An attempt is made to remove as much internally scattered light as possible by fitting a smooth function to the dark areas of the images and using a one-dimensional interpolation scheme to estimate the scattered light levels in the areas covered by the spectra. The two-dimensional frames are then trimmed into new two-dimensional frames including only fringe spectra.

2. *Flat-fielding.*—Pixel-to-pixel sensitivity variations are corrected by dividing the data by a flat-field calibration image taken with a tungsten lamp. The irregular illumination of the spectrum is repaired by the application of a “self-illumination correction” algorithm. This process constructs a second flat field by extracting the underlying illumination function from each individual image (see van Eyken et al. 2004a).

3. *Slant correction.*—An algorithm is applied to correct for misalignment of the spectral lines with the rows/columns of the CCD. This feature is caused by a combination of imperfect alignment of the CCD and by aberration and distortion in the instrument optics (i.e., a simple rotation will not correct the alignment over the entire detector). This step is essential for obtaining the proper cuts along the wavelength channels required to obtain uniform fringes.

4. *Low pass filtering.*—Finally, a one-dimensional, low-pass Fourier filter is applied to the data in the dispersion direction. This action removes the interferometer comb, the pattern of parallel lines that is created by the continuum, and therefore contains no Doppler information.

*Phase and visibility determination.*—Once the initial image processing is complete, the phases and visibilities of each wavelength channel (column) are measured. This is achieved simply by fitting a sine wave to each wavelength channel in the image with a standard  $\chi^2$  minimization algorithm. The fit is weighted according to the number of counts in the original non-flat-fielded data, on the assumption of photon noise-dominated error.

To determine the phase accurately, two passes of the curve fitting are performed to determine the fringe frequency. The first pass determines the frequencies of each channel. A polynomial is then fit to the frequencies as a function of wavelength (weighted according to the measurement errors). The process is repeated a second time but with the frequencies fixed to match this function. This approach was found to significantly improve the final precision.

*Determining the intrinsic Doppler shift.*—Once the phase and visibility values are obtained for all wavelength channels, we combine them to form a vector versus wavelength channel called a whirl, where each vector represents the fringe amplitude and phase

<sup>3</sup> IRAF is distributed by the National Optical Observatory, which is operated by AURA, Inc., under contract with the National Science Foundation.

(see the definition in Erskine & Ge 2000). In general, the star+iodine data whirl will be a linear vector combination of the iodine and star template whirls, where the template whirls are rotated in phase by an amount that must be determined. A set of four simultaneous linear equations can be constructed for each pair of channels (Erskine 2003). The solution for the phase rotations is found by linearizing the complete overdetermined set of equations across all channels and using singular value decomposition. This procedure returns a “best-fit solution” along with standard error estimates. The measured rotations correspond to the star shift and the intrinsic instrument shift. The difference between these two rotations yield the intrinsic stellar RV shift.

In addition to the two phase rotations, several additional degrees of freedom are allowed in our processing. In particular, we allow for bulk shift of the entire spectrum in the dispersion direction. This change can be produced by a Doppler shift or by movement of the CCD detector due to thermal flexure. This, along with additional flexures in the instrument optics, can create translations of the image. A reduced  $\chi^2$  value is determined between the star+iodine data and the best superposition of the pixel-shifted and rotated templates. This process is iterated until a minimum is reached in the reduced  $\chi^2$ .

After correcting for instrument drift, it still remains to apply a barycentric correction to the velocities to account for the motion of the Earth. This is done using our own software written in IDL. Diurnal motion is corrected using an algorithm adapted from the IRAF procedure `rvcorrect` in the NOAO package. Annual motion is corrected using the `baryvel` routine from the IDL astronomy library,<sup>4</sup> which is based on the algorithm from Stumpff (1980).

At the completion of the data processing, the 90 stars in the survey fell into three categories: (1) 75 of the stars exhibited less than  $2.5 \sigma$  RV scatter about a mean value, (2) 10 stars had RV variations between  $2.5 \sigma$  and  $1000 \text{ m s}^{-1}$  rms about the mean, and (3) 5 stars were spectroscopic binaries with RV variations larger than  $1000 \text{ m s}^{-1}$  rms. Only stars in the second group were considered candidates for harboring a planet, and of those 10 stars, HD 102195 appeared to be the most promising candidate.

#### 4. HD 102195

Having identified HD 102195 as the most promising planetary candidate star from our initial ET survey, we embarked on a series of additional observations of HD 102195 to determine the nature of the RV variations. We obtained further precision RV measurements as well as high-resolution spectroscopy, Ca II H and K emission-line spectroscopy, and high-precision photometry.

##### 4.1. Additional Radial Velocities

The initial 14 coudé measurements of HD 102195 with the ET had an rms variation of slightly more than  $60 \text{ m s}^{-1}$ , with typical single-measurement errors of  $20 \text{ m s}^{-1}$ . An additional 14 ET measurements were made in 2005 May with the KPNO 2.1 m telescope and the same ET instrument. Figure 2 displays all 28 spring 2005 ET radial velocities of the star and confirms HD 102195 as a good planetary candidate host star.

The KPNO 2.1 m ET system was used again in 2005 December to obtain an additional 21 RV measurements of HD 102195. We also acquired 10 RV measurements of the star between 2005 November and 2006 January with the High Resolution Spectrograph (HRS) of the HET (L. W. Ramsey et al. 2006, in preparation) to confirm the ET results. The HET HRS data were obtained with a  $2''$  fiber and exposure times of 10 minutes. These observations were conducted with the HRS  $R = 60,000$

FIG. 2.—Radial velocities for HD 102195, showing the 28 measurements from ET at the KPNO coudé feed/2.1 m in the spring of 2005. The rms errors for the ET measurements at KPNO are  $\sim 10$  and  $\sim 20 \text{ m s}^{-1}$  for the 2.1 m and coudé feed, respectively. The solid line is the Keplerian orbital fit to the observed data.

cross-dispersed echelle mode. This is the standard HRS configuration for precision RV measurements, and the data were processed with the techniques described in Cochran et al. (2004). The HET observations, which have typical internal errors of  $\sim 2 \text{ m s}^{-1}$ , were able to be timed for maximum phase leverage because of the queue-scheduled operation of the telescope. All 59 precision RV measurements of HD 102195 from all sources are presented in Table 1.

##### 4.2. High-Resolution Spectra

A total of nine high-resolution ( $R = 150,000$ ) spectra of HD 102195 were obtained with the SARG spectrograph on the 3.5 m Telescopio Nazionale Galileo at La Palma on 2005 June 19, 20, and 21. The wavelength coverage is complete from 3700 to  $10000 \text{ \AA}$ . These data were used to monitor line-bisector variations, to determine stellar properties (metallicity,  $\log g$ ,  $T_{\text{eff}}$ , and  $v \sin i$ ), and to search for any evidence of a second set of lines in the system. The SARG spectra were processed through a data pipeline developed by J. Valenti for the N2K Consortium short-period planet survey (Valenti & Fischer 2005). Figure 3 shows a section of the SARG data centered at a wavelength of  $6140 \text{ \AA}$ . The typical signal-to-noise ratio (S/N) for each spectrum is about  $100 \text{ pixel}^{-1}$ . The nine spectra were normalized and fitted with synthetic spectra to derive the stellar parameters. The average values of the derived parameters are reported in § 5.1. The nine spectra were searched for line bisector variations, but no significant variations were found over the 3 days. For instance, the average bisector velocity span for each day is  $-1.9 \pm 12.4 \text{ m s}^{-1}$ ,  $5.2 \pm 12.0 \text{ m s}^{-1}$ , and  $23.6 \pm 11.7 \text{ m s}^{-1}$  for June 19, 20, and 21, respectively. Details on the line bisector analysis can be seen in Martínez Fiorenzano et al. (2005).

In addition, one high-resolution spectrum of HD 102195 was obtained with the 2.2 m telescope at the German Spanish Astronomical Observatory (CAHA; Almería, Spain) on 2006 January 14. The Fiber Optics Cassegrain Echelle Spectrograph (FOCES; Pfeiffer et al. 1998) was used with a  $2048 \times 2048 \text{ } 24 \mu\text{m}$  SITE 1d15 CCD detector. The wavelength range covers from 3500 to  $10700 \text{ \AA}$  in 111 orders. The reciprocal dispersion ranges from  $0.04$  to  $0.13 \text{ \AA pixel}^{-1}$ , and the spectral resolution, determined as the FWHM of the arc comparison lines, ranges from  $0.08$  to  $0.35 \text{ \AA}$ . A signal-to-noise ratio of  $100 \text{ pixel}^{-1}$  was obtained in the  $\text{H}\alpha$  line region.

<sup>a</sup> CF = 0.9 m coudé Feed; BK = Block.

The spectra have been extracted using the standard reduction procedures in the IRAF package (bias subtraction, flat-field division, and optimal extraction of the spectra). The wavelength calibration was obtained by taking spectra of a Th-Ar lamp. Finally, the spectra have been normalized by a polynomial fit to the observed continuum. This spectrum was used to determine stellar properties, analyze the chromospheric activity, and estimate the age from the lithium line (Li I  $\lambda 6707.8$ ).

#### 4.3. Ca II H and K Observations

HD 102195 was observed between 2005 December 14 and 20 with the KPNO 0.9 m coudé spectrograph to monitor the emission at the core of the Ca H and K lines. The observations were obtained with Grating A, Camera 5, the long collimator, a 400  $\mu$ m slit, and a 2K  $\times$  2K CCD camera. This configuration produced a spectral resolving power of 10,000 over a wavelength range of 230 Å centered on 4010 Å. A total of 29 spectra were obtained during the run. The spectra were processed with standard IRAF procedures. A reference star,  $\tau$  Ceti, was monitored for comparison. Emission is clearly seen in the core of the Ca II H and K lines (see Fig. 4), as expected by the classification of this star as mildly active by Strassmeier et al. (2000).

#### 4.4. High-Precision Photometry

Between 2005 April and 2006 February, we obtained high-precision photometry of HD 102195 with the T10 0.8 m automatic photometric telescope (APT) at Fairborn Observatory.

These observations covered the last part of the 2004–05 and the first part of the 2005–06 observing seasons. The APTs can detect short-term, low-amplitude brightness variability in the stars caused by rotational modulation in the visibility of magnetic surface features such as spots and plagues (e.g., Henry et al. 1995), as well as longer term variations associated with stellar magnetic cycles (Henry 1999). Thus, photometric observations can help to establish whether observed radial velocity variations are caused by stellar activity or planetary-reflex motion (e.g., Henry et al. 2000a). Queloz et al. (2001) and Paulson et al. (2004) have found several examples of periodic radial velocity variations in solar-type stars caused by photospheric spots and plagues. The APT observations are also useful to search for possible transits of the planetary companions (Henry et al. 2000b; Sato et al. 2005).

The T10 APT is equipped with a two-channel precision photometer containing two EMI 9124QB bi-alkali photomultiplier tubes to make simultaneous measurements in the Strömgren  $b$  and  $y$  passbands. The APT measures the difference in brightness between a program star and one or more nearby comparison stars. The primary comparison star used for HD 102195 was HD 102747 ( $V = 7.77$ ,  $B - V = 0.513$ , F5); a secondary comparison star was HD 101730 ( $V = 6.94$ ,  $B - V = 0.49$ , F5). Strömgren  $b$  and  $y$  differential magnitudes were computed and corrected for differential extinction with nightly extinction coefficients and transformed to the Strömgren system with yearly mean transformation coefficients. Finally, we combined the Strömgren  $b$  and  $y$  differential magnitudes into a single  $(b + y)/2$  passband to maximize the precision of the photometric measurements. The

FIG. 3.—Part of the combined normalized observed spectrum and superimposed synthetic spectrum of HD 102195 for four different wavelength intervals. The black lines are the observed data. The gray lines are the synthetic data. The spectral resolution is  $R = 150,000$  ( $\sim 0.02$  Å pixel<sup>-1</sup>) and an average  $S/N \sim 300$  pixel<sup>-1</sup> in the combined continuum spectrum. The synthetic spectrum is produced by a model using the stellar parameters in Table 3. [See the electronic edition of the *Journal* for a color version of this figure.]

typical external precision of the differential magnitudes is 0.0012–0.0016 mag for this telescope, as determined from observations of pairs of constant stars. The standard deviation of our comparison star 2 minus comparison star 1 differential magnitudes is 0.0019, close to the typical precision and indicating very little variability in either comparison star. However, the HD 102195 minus com-

parison star 1 differential magnitudes have standard deviations of 0.0048 and 0.0033 mag in observing seasons 1 and 2, respectively, indicating clear variability in HD 102195. The 468 individual differential magnitudes of HD 102195 minus the primary comparison star are given in Table 2. Further information on the automatic telescope, photometer, observing procedures, and data

FIG. 4.—Typical Ca II H and K emission line spectrum of HD 102195 taken with the KPNO 0.9 m coude long-slit spectrograph after the background is subtracted and the flux is summed. The spectral resolution is  $R = 10,000$ . H and K emission lines are clearly visible in the core of the broad H and K absorption lines.

reduction techniques can be found in Henry (1999) and Eaton et al. (2003).

## 5. RESULTS

### 5.1. Stellar Properties

HD 102195 was identified as a K0 V star with a color of  $(B - V) = +0.84$  (Strassmeier et al. 2000). The *Hipparcos* parallax (ESA 1997) of  $34.51 \pm 1.16$  mas places this target at 29 pc. The apparent visible magnitude is  $V = 8.05 \pm 0.03$  measured from the APT photometry. The absolute magnitude is  $M_V = 5.73$ . Montes et al. (2001a) suggest that HD 102195 may belong to the Local Association, which, if confirmed, would place the age of the star at 20–150 Myr. Following the procedure described in Valenti & Fischer (2005), our spectroscopic analysis of the SARG spectra ( $R \sim 150,000$ ) yields  $T_{\text{eff}} = 5330 \pm 28$  K,  $[\text{Fe}/\text{H}] = 0.096 \pm 0.032$ ,  $\log g = 4.368 \pm 0.038$  [ $\log(\text{cm s}^{-2})$ ], and  $v \sin i = 3.23 \pm 0.07$  km s $^{-1}$ . The fit of this model to the combined spectrum is shown in Figure 3. The effective temperature and surface gravity of the star appears to be consistent with a G8 V.

We interpolated the “high temperature” table of Vandenberg & Clem (2003) as a function of spectroscopic effective temperature, gravity, and iron abundance to obtain a  $V$ -band bolometric correction of  $-0.177$ . Applying this correction to the observed  $V$ -band magnitude of  $8.05 \pm 0.03$  yielded a stellar luminosity of  $0.463 \pm 0.034 L_{\odot}$ .

We used our spectroscopically determined  $[\text{Ti}/\text{Fe}]$  abundance ratio as a crude measure of  $\alpha$ -element enrichment, obtaining

TABLE 3

Age .....	0.6–4.2 Gyr

$0.049 \pm 0.042$ . We detect no significant  $\alpha$ -element enhancement, but for consistency with Valenti & Fischer (2005), we used our measured  $\alpha$ -element enhancement of 0.049 when interpolating the  $Y^2$  isochrones, slightly perturbing our derived stellar properties.

We used the stellar luminosity and the spectroscopic effective temperature, iron abundance, and  $\alpha$ -element enrichment to interpolate the  $Y^2$  isochrones (Demarque et al. 2004), obtaining a stellar mass of  $0.926 M_{\odot}$  and a stellar radius of  $0.835 R_{\odot}$ . In addition, the most probable age is 2.0 Gyr with an asymmetric  $1 \sigma$  confidence interval spanning the range 0.6–4.2 Gyr. This age estimate is much older than that derived from the Local Association by Montes et al. (2001a). The chromospheric activity of HD 102195 has been measured by Strassmeier et al. (2000). The chromospheric emission ratio,  $\log R'_{\text{HK}} = -4.30$ , indicates that this is a mildly active star (Noyes et al. 1984). The stellar parameters are summarized in Table 3.

Further analysis of the FOCES high-resolution optical spectrum of HD 102195 was conducted to independently derive the stellar properties. Here we summarize the results.

**Spectral type.**—To obtain an independent estimate of the spectral type of this star, we have compared the spectrum of HD 102195 with that of inactive reference stars taken during the same observing run. The analysis makes use of the program STARMOD developed at Penn State University (Barden 1985) and modified more recently by us. With this program a synthetic stellar spectrum is constructed from the artificially rotationally broadened and radial-velocity-shifted spectrum of an appropriate reference star. We obtained the best fit between observed and synthetic spectra when we use a G8-dwarf spectral type standard star (HD 182488). The uncertainty in this classification is of one spectral subtype as is typical in the MK spectral classification. The careful analysis of the wings of the  $H\alpha$  and  $\text{Na I } D_1$  and  $D_2$  lines clearly indicates a better fit with a G8 V than with a K0 V. This spectral classification agrees with the results of the spectral synthesis of the SARG spectra.

**Rotational velocity.**—By using the program STARMOD we have obtained the best fits with  $v \sin i$  values between 3 and 4 km s $^{-1}$ . In order to determine a more accurate rotational velocity of this star, we have made use of the cross-correlation technique by using the routine `fxcor` in IRAF. When a stellar spectrum with rotationally broadened lines is cross-correlated against a narrow-lined spectrum, the width of the cross-correlation function (CCF)

NOTES.—Table 2 is presented in its entirety in the electronic edition of the *Astrophysical Journal*. A portion is shown here for guidance regarding its form and content.

is sensitive to the amount of rotational broadening of the first spectrum. Thus, by measuring this width, one can obtain a measurement of the rotational velocity of the star. The observed spectrum was *cross-correlated* against the spectrum of a template star (the G8 V star HD 182488) and the width (FWHM) of CCF determined. The rotational velocity of HD 182488 is  $0.6 \pm 0.5 \text{ km s}^{-1}$ ; this value has been determined by Fekel (1997) using a method based on the determination of the intrinsic stellar broadening from the observed FWHM of weak or moderate-strength lines, corrected from instrumental profile and from macroturbulent broadening. The calibration of this width to yield an estimate of  $v \sin i$  is determined by cross-correlating artificially broadened spectra of the template star with the original template star spectrum. The broadened spectra were created for  $v \sin i$  spanning the expected range of values by convolution with a theoretical rotational profile (Gray 1992) using the program *STARMOD*. The resulting relationship between  $v \sin i$  and FWHM of the CCF was fitted with a fourth-order polynomial. The  $v \sin i$  obtained in this way for HD 102195 is  $3.7 \pm 0.6 \text{ km s}^{-1}$ , which is in good agreement with the value derived from the SARG spectra.

*Radial velocity.*—The previous known value of the heliocentric radial velocity of this star is  $2.1 \pm 0.6 \text{ km s}^{-1}$ , a weighted mean value of the two measurements reported by Strassmeier et al. (2000).

In the FOCES spectrum the heliocentric radial velocity has been determined by using the cross-correlation technique. The spectrum of HD 102195 was cross-correlated order by order, by using the routine *fxcor* in IRAF, against the spectrum of the K0 V radial velocity standard HD 3651 (Barnes et al. 1986). We have used the K0 V star HD 3651 because the G8 V star HD 182488 was not observed in the same observing run as that for HD 102195. However, we have also determined the radial velocity using HD 182488, and the result is very similar. The radial velocity was derived for each order from the peak of the cross-correlation function peak (CCF), and the uncertainties were calculated by *fxcor* based on the fitted peak height and the antisymmetric noise as described by Tonry & Davis (1979). Those orders that contain chromospheric features and prominent telluric lines have been excluded when determining the mean velocity. The resulting value is  $V_{\text{hel}} = 2.04 \pm 0.07 \text{ km s}^{-1}$ .

*Kinematics and age.*—The galactic space-velocity components ( $U$ ,  $V$ ,  $W$ ) have been determined by Montes et al. (2001a) using heliocentric radial velocity of  $2.1 \pm 0.6 \text{ km s}^{-1}$  (Strassmeier et al. 2000) and the precise proper motions taken from *Hipparcos* (ESA 1997) and *Tycho-2* (Høg et al. 2000) catalogs. Solely on the basis of kinematics criteria, Montes et al. (2001a) classified HD 102195 as a young disk star and a possible member of the Local Association moving group. The age of this complex moving group is in the range of 20–150 Myr; however, the age inferred from the lithium line strength does not agree with such a young age.

As is well known, the Li I line at  $\lambda 6708 \text{ \AA}$  is an important diagnostic of age in late-type stars, since it is easily destroyed by thermonuclear reactions in the stellar interior (e.g., Soderblom et al. 1990). In the FOCES spectrum a small absorption Li I line is observed blended with the nearby Fe I  $\lambda 6707.41 \text{ \AA}$  line. We have corrected the total measured equivalent width (EW) (Li I+Fe I) =  $17.4 \text{ m\AA}$ , by subtracting the EW of Fe I calculated from the empirical relationship with  $(B-V)$  given by Soderblom et al. (1993). Very similar results are also obtained using the empirical relationship given by Favata et al. (1993). The resulting corrected EW(Li I) is  $2.8 \text{ m\AA}$ , in agreement with the value previously reported by Strassmeier et al. (2000) of  $3 \text{ m\AA}$ .

Comparing the EW(Li I) of HD 102195 with those of well-known young open clusters of different ages in a EW(Li I) versus

spectral type diagram (Montes et al. 2001a, 2001b and references therein), a much greater age than the Local Association is inferred; it could be even older than the Hyades. This result and the relatively low level of chromospheric activity (see below) favor the range of age deduced from the Y2 isochrones.

*Chromospheric activity indicators.*—The FOCES 2006 January 14 echelle spectrum of HD 102195 allows us to study the behavior of the different chromospheric activity indicators from the Ca II H and K to the Ca II infrared triplet (IRT) lines, which are formed at different atmospheric heights. The chromospheric contribution in these features has been determined by using the spectral subtraction technique (see Montes et al. 2000). The spectral subtraction technique is the subtraction of a synthesized stellar spectrum constructed from an artificially rotationally broadened and radial velocity-shifted spectrum of an inactive star chosen to match the spectral type and luminosity class of the active star under consideration. The synthesized spectrum was constructed using a G8 V reference star with the program *starmod*.

In the observed spectrum only the Ca II H and K lines are clearly detected in emission. After applying the spectral subtraction, a small excess chromospheric emission is detected in the H $\alpha$  and Ca II IRT ( $\lambda 8498$ ,  $\lambda 8542$ ,  $\lambda 8662$ ) lines. However, the other Balmer lines, as well as the Na I  $D_1$  and  $D_2$  lines, do not show evidences of filled-in absorption by chromospheric emission.

In Table 4 we give the excess emission equivalent width (EW) (measured in the subtracted spectra) for the Ca II H and K, H $\alpha$  and Ca II IRT lines and the corresponding absolute chromospheric flux at the stellar surface ( $\log F_S$  [ $\text{ergs cm}^{-2} \text{ s}^{-1}$ ]) obtained by using the calibration of Hall (1996) as a function of  $(B-V)$ . For instance, the calibration of Hall (1996) gives the flux in the continuum at the wavelengths  $3950 \text{ \AA}$  (for the Ca II H and K lines),  $6563 \text{ \AA}$  (H $\alpha$  line), and  $8520 \text{ \AA}$  (Ca II IRT lines) as a function of  $B-V$ . Using this flux in the continuum we convert the EW into  $\log F$  values. The uncertainties in the measured EW were estimated to be in the range 10%–20% taking into account (1) the typical internal precisions of *STARMOD*, (2) the rms obtained in the fit between observed and synthesized spectra in the spectral regions outside the chromospheric features, and (3) the standard deviations resulting in the EW measurements.

The chromospheric activity index ( $R'_{\text{HK}}$ ) obtained from the stellar surface in the Ca II H and K lines (which is corrected from

the photospheric contribution by using the spectral subtraction) is  $\log R'_{\text{HK}} = -4.45$ , similar to the value of  $-4.3$  reported by Strassmeier et al. (2000).

It is well known that the chromospheric activity is related to both the spectral type and rotational velocity. Late spectral type main-sequence stars have larger chromospheric emission than early stars, and as the star ages, it slows down its rotation and decreases the level of activity. In this sense the chromospheric activity provides an indication of the stellar age for a given spectral type. Using the calibration of Soderblom et al. (1991) for the chromospheric activity (measured by  $R'_{\text{HK}}$ )/age relation, an age of 0.8 Gyr is inferred. This age is only an estimate, since these kinds of calibrations are strictly valid for chromospherically quiet stars ( $\log R'_{\text{HK}} < -4.75$ ; see Saffe et al. [2005] for a discussion) but agree with the age deduced from the Li I line, and it is in the range of ages deduced from the Y2 isochrones.

### 5.2. RV Analysis and Orbital Solution

The RV precision and stability of ET have been determined using the RV stable stars in our survey. We define RV stable stars (at our precision level) to be those stars that show a reduced  $\chi^2 < 2$  to the fit of a constant RV value over the period of observation (typically  $\sim 10$  days). At the 0.9 m coudé during a typical observing block, seven of 15 search stars satisfied this criterion. For those, we found a rms scatter of  $18.9 \text{ m s}^{-1}$  at a mean visual magnitude of 8.26 and typical exposure times of 20–30 minutes. Using the same criterion for the 2.1 m observations, we found 12 of 24 stars to be RV-stable. These stable stars had a mean standard deviation of  $17.6 \text{ m s}^{-1}$  about a constant RV. For the 2.1 m targets, which had  $\langle V \rangle = 8.48$ , the typical exposure times were 10 minutes. For both configurations, the errors are consistent with the expected photon noise limit. For an independent check of the instrument, we were able to recover the RV curve for 51 Peg. Figure 1 shows the coudé feed results for 51 Peg with the predicted RV curve due to the 4.23 day companion 51 Peg b. The measured residual mean error (after the expected velocity induced by the planet) for the coudé feed observations of 51 Peg is  $7.9 \text{ m s}^{-1}$ , which is consistent with the photon noise limit.

A total of 59 radial velocities of HD 102195 have been obtained from 2005 January through 2006 January. In contrast with the stable stars, the velocity variability of HD 102195 is  $\sim 60 \text{ m s}^{-1}$ ,  $3 \sigma$  above the measurement noise for the ET measurements at the KPNO coudé,  $6 \sigma$  above the noise level of the ET measurements at the KPNO 2.1 m, and approximately 30 times larger than the measurement noise for the HET/HRS measurements (see Table 1). A periodogram analysis was carried out with a RV fitting code running a combination of a Lomb-Scargle (L-S) periodogram (Lomb 1976; Scargle 1982) and an iterative grid-search algorithm to locate the best fit to the data. The interactive grid search is the method used to search parameter space for the best-fitting model by adjusting model parameters until it converges on a solution. Figure 5 displays the L-S periodogram resulting from a Fourier analysis of the HD 102195 velocities. The horizontal dotted lines correspond to the false-alarm probabilities for a given L-S statistic (or power). A strong peak is found at a period of 4.11 days. The false alarm probability associated with this peak is  $< 10^{-6}$ .

We performed a Bayesian analysis of the RV data to identify whether a planetary companion is present and determine their orbital parameters, following the methods in Ford (2005, 2006). The RV variations are modeled as a single planet on a circular orbit. We assume a prior  $p(P, K, \phi, C, \sigma_j) \sim [P(K + K_0)\sigma_j]^{-1}$ , where  $P$  is the orbital period,  $K$  is the velocity semi-amplitude,  $\phi$  is the orbital phase at the given epoch,  $C_i$  is the  $i^{\text{th}}$  constant velocity offset,

FIG. 5.—Periodogram of the velocities for HD 102195, showing peak power at 4.11 days with a false alarm probability  $\sim 10^{-6}$ .

and  $\sigma_j$  is the magnitude of the stellar jitter. We impose sharp cut-offs on the prior at  $P_{\text{min}} = 1$  day,  $P_{\text{max}} = 3$  yr,  $K_{\text{max}} = 2 \text{ km s}^{-1}$ ,  $\sigma_{j,\text{min}} = 1 \text{ m s}^{-1}$ , and  $\sigma_{j,\text{max}} = 1 \text{ km s}^{-1}$ . A modified Jeffery's prior is used for the velocity semi-amplitude to make the prior for  $K$  normalizable, and we choose a scale parameter of  $K_0 = 1 \text{ m s}^{-1}$ . Our model also includes five velocity offsets,  $C_i$ , that are necessary due to the use of different velocity zero points for the various instruments and observing runs. We assume that each observation has an independent Gaussian observational uncertainty,  $\sigma_{i,\text{obs}}$ , that is estimated from the photon statistics. We calculate the likelihood using an effective uncertainty of  $\sigma_{i,\text{eff}} = (\sigma_{i,\text{obs}}^2 + \sigma_j^2)^{1/2}$  for each observation. To calculate the posterior probability distribution function, we analytically integrate over all but two of the model parameters using the Laplace and WKB approximations. Then we directly integrate over the two remaining model parameters,  $P$  and  $\sigma_j$ .

In Figure 6 we show the posterior probability density function (posterior PDF) marginalized over all model parameters except the orbital period, analyzing the observations from each observatory separately. The 14 observations with ET at the KPNO 0.9 m coudé feed have a significantly larger measurement uncertainty than the other observations and do not isolate a single orbital solution (*upper middle panel*). On the basis of these observations, we obtained 35 observations with the ET at the KPNO 2.1 m. Analysis of the velocities from the 2.1 m alone shows a  $\geq 99.9\%$  posterior probability of having a periodic signal (compared with a constant velocity or quadratic trend), and a  $\geq 99.3\%$  posterior probability integrated over all solutions contained in the peak at 4.1 days (*lower middle panel*). Using early observations with the 2.1 m, we obtained 10 additional very high precision radial velocity measurements using the echelle spectrograph on HET. The HET observations by themselves (*bottom panel*) display the same periodicity as that found in the KPNO/ET observations. Combining all the radial velocity observations (*top panel*), we find that there is a single dominant peak at 4.11 days that we interpret as the result of perturbations by a  $m \sin i \simeq 0.49 M_J$  planet.

In Figure 7 we show the marginalized posterior PDF combining all radial velocity observations. The posterior probability is dominated by one peak at  $P = 4.11$  days that contains essentially all of the posterior probability. The peak near 1.3 days is a result of aliasing due to the day/night cycle and contains  $\leq 10^{-9}$  of the posterior probability. The peak near 4.8 days shown in the coudé feed data (*see inset*) is the result of aliasing due to the lunar

FIG. 6.—Posterior probability density function marginalized over all model parameters except for the orbital period for RV data taken at different telescopes. [See the electronic edition of the *Journal* for a color version of this figure.]

cycle (most observations occur near the full moon) and contains only  $\leq 10^{-18}$  of the posterior probability. Our best-fit solution has  $P = 4.11453$  days,  $K = 63.2 \text{ m s}^{-1}$ ,  $\sigma_j = 5.9 \text{ m s}^{-1}$ , and an rms of  $16.0 \text{ m s}^{-1}$ . We have also performed a Bayesian analysis using a full Keplerian model and the Markov chain Monte Carlo (MCMC) technique (Ford 2005). The present observations do not provide a significant detection of an orbital eccentricity but do place upper limits on the allowed eccentricities. Marginalizing over all model parameters, we estimate that  $\langle P \rangle \simeq 4.11434 \pm$

FIG. 7.—Marginalized posterior PDF combining all RV data taken at the coude feed, 2.1 m, and the HET. Nearly all of the power is in the 4.11 day period; there is no indication of any significant RV variation at the 12.3 day photometric period.

TABLE 5  
ORBITAL PARAMETERS FOR HD 102195b

Parameter	Value
$P$ .....	$4.11434 \pm 0.00089$ days
$T_p$ .....	$2453732.7 \pm 0.5$
$e$ .....	$< 0.14$
$a$ .....	$0.0491 \text{ AU}$
$\omega$ .....	$143^\circ \pm 15^\circ$
$K$ .....	$63.4 \pm 2.0 \text{ m s}^{-1}$
$m \sin i$ .....	$0.488 M_J \pm 0.015 M_J \text{ } (M_*/0.93 M_\odot)$
$\sigma_j$ .....	$5.8 \pm 1.8 \text{ m s}^{-1}$
rms.....	$16.0 \text{ m s}^{-1}$

$0.00089$ ,  $\langle K \rangle \simeq 63.4 \pm 2.0 \text{ m s}^{-1}$ , and  $\langle \sigma_j \rangle \simeq 5.8 \pm 1.8 \text{ m s}^{-1}$ . Our MCMC simulations find a 5% posterior probability for all eccentricities larger than 0.096 and a 0.1% posterior probability for all eccentricities greater than 0.14. Table 5 summarizes the orbital parameters for HD 102195b.

An independent RV curve fitting was conducted using the *Gaussfit* software developed by part of the *HST* FGS science team (e.g., Jefferys et al. 1987; McArthur et al. 1994; Cochran et al. 2004). This software uses a robust estimate method to find the combined orbital solution, where the offsets from different data sets are included as free parameters for fitting. Figure 8 shows the best-fit RV curve. The planet has a  $4.1134 \pm 0.0009$  day orbital period, which is consistent with the derived values from the L-S periodogram and also the Bayesian analysis. This analysis finds a solution with a minimum planet mass of  $0.49 M_J$  in a nearly circular orbit with an eccentricity of  $0.06 \pm 0.02$ . These values are in excellent agreement with the Bayesian analysis above. The semimajor axis has a minimum size of 0.049 AU.

The companion's mass is similar to other known hot-Jupiter exoplanets with similar orbital periods around solar-type stars.

FIG. 8.—Phased radial velocities for HD 102195. The KPNO coude data are filled circles, the KPNO 2.1 m data are filled triangles, and the HET data are open circles. Two orbital cycles are shown, and each observation is plotted as two points. The best fit to the data yields an orbital period of 4.11434 days and a velocity semiamplitude of  $63.4 \text{ m s}^{-1}$ . If the stellar mass is  $0.93 M_\odot$ , the derived minimum planetary mass is  $0.488 M_J$  and the minimum orbital radius is 0.0491 AU. [See the electronic edition of the *Journal* for a color version of this figure.]

FIG. 9.—*Top*: Strömgren  $(b+y)/2$  photometric observations of HD 102195 obtained at the end of the 2004–2005 observing season with the T10 0.8 m APT at Fairborn Observatory. A cyclic variation of about 0.015 mag in the brightness of the star is easily seen. *Bottom*: Power spectrum of the observations in the top panel. A clear period of 12.3 days is interpreted as the rotation period of the star.

The low eccentricity is not surprising since tidal circularization is expected for such a close planetary companion.

### 5.3. Photometric Analysis

Plots of the T10 APT photometric measurements from the 2004–05 and 2005–06 observing seasons are shown in Figures 9 and 10, respectively. Although the observations from 2004 to 2005 are relatively few (38), the photometric amplitude of HD 102195 was greater at that time. The top panel of Figure 9 clearly shows cyclic variability with an amplitude of around 0.015 mag. The power spectrum of these data is shown in the bottom panel of Figure 9 and gives a period of  $12.3 \pm 0.3$  days, which we take to be the rotation period of the star made apparent by rotational modulation in the visibility of photospheric starspots. The light curve closely resembles those of other spotted stars (e.g., Henry et al. 1995).

The top panel in Figure 10 plots all the photometric data for the 2005–2006 observing season. A power spectrum of these second season observations exhibits the same 12.3 day periodicity but with much lower amplitude. The observations in this figure are plotted against planetary orbital phase computed from the orbital elements in Table 5; zero phase refers to a time of inferior conjunction (mid-transit). A least-squares sine fit to the brightness measurements in the top panel gives a semi-amplitude of only  $0.0004 \pm 0.0002$  mag. Given the cycle-to-cycle variation in the light curve caused by a continually evolving starspot distribution, this small amplitude on the radial velocity period is consistent with *no* brightness variability on that period. Thus, the photometry supports planetary reflex motion as the cause of the radial velocity variability.

Since the 2005–2006 brightness measurements are both more numerous and exhibit lower variability than the observations of the previous season, the observations from the second season are more suitable for seeking possible transits of the planet across the disk of the star. The solid curve in each panel of Figure 10 ap-

FIG. 10.—*Top*: Strömgren  $(b+y)/2$  photometric observations of HD 102195 obtained during the 2005–2006 observing season with the T10 0.8 m APT at Fairborn Observatory and plotted against orbital phase of the planetary companion. The predicted time, depth, and duration of possible transits are shown schematically. The star exhibits no optical variability on the radial velocity period larger than 0.0004 mag or so. *Bottom*: Observations around the predicted time of transit are replotted with an expanded scale on the abscissa. The error bars are described in the text. Even very shallow transits are ruled out by these observations.

proximates the predicted transit light curve, assuming a planetary orbital inclination of  $90^\circ$  (central transits). The out-of-transit light level corresponds to the mean brightness of the observations. The transit duration is estimated from the orbital elements, while the transit depth is derived from the estimated stellar radius (Table 3) and an assumed planetary radius equal to Jupiter's. The bottom panel of Figure 10 shows the observations around the predicted time of mid transit replotted with an expanded scale on the abscissa. The horizontal error bar below the predicted transit curve represents the estimated uncertainty in the time of mid transit, based on the orbital elements. The vertical error bar represents the 0.0019 mag precision of the observations.

These 2005–2006 photometric observations of HD 102195 cover the predicted transit window quite well and reveal no sign of a transit. The 47 observations within the transit window in the bottom panel of Figure 10 have a mean brightness level of  $0.3683 \pm 0.0005$  mag. The 383 observations outside the transit window have a mean of  $0.3676 \pm 0.0002$  mag. Therefore, the mean brightness values inside and outside of the transit window agree to within 0.0007 mag, i.e., to within their respective uncertainties. Our photometric observations rule out even very shallow transit events.

## 6. DISCUSSION

HD 102195 is a mildly active G8 V dwarf. Stellar activity such as starspots introduces jitter into the RV measurements. The amplitude of the stellar jitter caused by stellar activity can be estimated from the previously derived formula of Santos et al. (2000). Using the measured chromospheric activity index,  $R'_{HK} = 5 \times 10^{-5}$ , we estimate that the rms RV jitter should be  $\sim 19 \text{ m s}^{-1}$ . This level is consistent with the estimate from the Bayesian analysis of the radial velocity observations. On the basis of previous RV studies of active G dwarfs with photometric variations similar to HD 102195 (e.g., Paulson et al. 2004; Santos et al. 2000),

we expect that the semiamplitude of the starspot-induced radial velocity variation for HD 102195 may be on the order of  $\sim 10$ – $20 \text{ m s}^{-1}$ . Even if the photometric and RV periods were equal, the deduced level of stellar activity could not account for the observed RV variations in HD 102195. This strengthens the conclusion from § 5.3 that stellar activity is not responsible for the 4.11 day radial velocity variation.

It is unusual (and of some concern) that the 12.3 day photometric period appears to be exactly (at least within the measurement errors) 3 times that of the 4.11 day radial velocity period. Could three similar starspot groups spaced approximately  $120^\circ$  in longitude on the star be responsible for the observed radial velocity period? Figure 9 shows that there is essentially no power in the brightness variations at 4.11 days (corresponding to a frequency of  $0.24 \text{ cycles day}^{-1}$ ). Conversely, an examination of Figure 7 shows that there is essentially no power in the radial velocity variations at the photometric period of 12.3 days. This mismatch of the photometric and radial velocity periods indicates that they arise from separate causes and supports the planetary interpretation.

The Ca II H and K emission measurements also support the planetary interpretation of the RV variations in HD 102195. The standard technique for analyzing stellar H and K emission is the  $S$  index described by Duncan et al. (1991). This quantity is defined by Duncan et al. as  $S = (H + K)/(V + R)$ , where  $V$  and  $R$  are the summed flux in unnormalized  $20 \text{ \AA}$  wide continuum bands extending  $3891$ – $3911$  and  $3991$ – $4011 \text{ \AA}$ , respectively, and  $H$  and  $K$  are channels centered on the cores of the Ca II H and K and have a measured triangular instrument response of FWHM  $1.09 \text{ \AA}$ . For our  $S$  index measurements using spectra obtained at the KPNO  $0.9 \text{ m}$  coude telescope we define the quantities  $V$  and  $R$  in the same way as Duncan et al. (1991) but differ in our definition of the quantities  $H$  and  $K$ , which we define as the integrated flux in  $1.4 \text{ \AA}$  bands centered on the Ca II H and K lines. We call the resulting  $S$  index  $S_{\text{coude}}$  to differentiate it from the Mount Wilson  $S$  index. No attempt has been made to put  $S_{\text{coude}}$  on the Mount Wilson scale, since we are only interested in the variability of  $S_{\text{coude}}$ . The analysis of the chromospheric activity traced by the  $S$  index does not show any variability at the 4.11 day period of the planet but does display longer term changes that appear consistent with the photometric rotation period (see Fig. 11). The mean  $S_{\text{coude}}$  index for the entire run is measured to be  $0.024$  and varies from  $0.023$  to  $0.025$ . For comparison, in the reference star, Tau Ceti, the  $S$  index measurement varies less than  $0.0005$ . This result further suggests that stellar activity is not the source of the detected RV signals.

In addition, the stellar rotation period measured from the photometry is consistent with the projected rotation velocity measured from the spectral analysis of the SARG and FOCES high-resolution spectra. The measured  $v \sin i = 3.23 \pm 0.07 \text{ km s}^{-1}$  corresponds to a maximum rotation period of  $13.1 \pm 0.3$  days if a stellar radius of  $0.84 R_\odot$  is adopted. This does indicate that the stellar rotation axis may be close to an inclination of  $90^\circ$ . However, as discussed in § 5.3 above, photometric transits have been ruled out by our photometry.

This planetary detection is the first time an extrasolar planet has been discovered via RV variations around a star fainter than  $V = 8$  with a submeter aperture telescope. This discovery was made possible by the high throughput of the ET instrument. The total measured system detection efficiency of  $18\%$  (from the telescope to the detector) or  $49\%$  (from the fiber output to the detector) is about 4 times higher than has been achieved with HARPS, a state-of-the-art echelle spectrograph being used on the ESO  $3.6 \text{ m}$  telescope (Pepe et al. 2002).

FIG. 11.—Measurements of the  $S_{\text{coude}}$  index (bottom) and RV (top) during the same observation run at Kitt Peak.

Future DFDI instruments promise additional capabilities. Due to the use of the single-order medium-resolution stellar spectra superimposed with interference fringes, this method can be easily modified to allow multiple-object Doppler measurements (Ge 2002). A prototype multi-object DFDI obtained data in the spring of 2005 with the SDSS telescope and demonstrated this feasibility (Ge et al. 2005).

In addition, for single-object observations, the single-order medium-resolution spectrograph can be replaced with a cross-dispersed echellette spectrograph to cover multiple orders of dispersed fringes to gain wavelength coverage. The echellette can also increase the spectral resolution due to its higher dispersion over the low single-order blazed grating. Since the Doppler sensitivity is roughly proportional to the square root of the spectral resolution and wavelength coverage (Ge 2002), it is likely that an ET interferometer coupled with a cross-dispersed echellette will increase the Doppler sensitivity by a factor of  $\sim 3$ – $5$  times over current designs.

In summary, the detection of a planet around HD 102195 with a DFDI instrument demonstrates that the new-generation, high-throughput interferometric Doppler method is an effective technique for identifying extrasolar planets. This approach offers a number of opportunities for high-precision RV measurements and planet surveys, especially for stars fainter than previous surveys with echelle Doppler instruments have reached. This technique may become a significant component in the effort to assemble the large sample of extrasolar planets required for a comprehensive characterization of these objects.

We are grateful to Stuart Shaklan, Michael Shao, Chas Beichman, Richard Green, Skip Andree, Daryl Wilmarth, and the KPNO staff for their generous support and advice and to Larry Molnar for his help in the early photometric data acquisition. The HET observations, whose timings were critical, were made possible by the dedicated efforts of the HET staff. We are indebted to Sara Seager and Eric Agol for a number of stimulating discussions. We thank Aldo Martínez Fiorenzano for helping the line bisector analysis of HD 102195. We appreciate many valuable comments made by the referee, which helped to improve the paper quality. This work is supported by the National Science Foundation grant AST 02-43090, JPL, Pennsylvania State University, and the University of Florida. S. M. and J. v. E. acknowledge the JPL Michelson Fellowship funded by NASA. G. W. H. is grateful

for the efforts of Lou Boyd at Fairborn Observatory and acknowledges support from NASA grant NCC5-511 and NSF grant HRD 97-06268. E. B. F. acknowledges the support of the Miller Institute for Basic Research. W. D. C., M. E., and R. A. W. were supported by NASA grants NNG04G141G and NNG05G107G to the University of Texas at Austin. The Hobby-Eberly Telescope (HET) is a joint project of the University of Texas at Austin, Pennsylvania State University, Stanford University, Ludwig-Maximilians-Universität München, and Georg-August-Universität Göttingen. The HET is named in honor of its principal benefactors, William P. Hobby and Robert E. Eberly. D. M. was supported by the Uni-

versidad Complutense de Madrid and the Spanish Ministerio de Educación y Ciencia (MEC), Programa Nacional de Astronomía y Astrofísica under grant AYA2005-02750. D. M. is grateful to Raquel M. Martínez, Jesús Maldonado, and Benjamín Montesinos for their help during the observations. FOCES high-resolution optical spectra were based on observations collected at the Centro Astronómico Hispano Alemán (CAHA) at Calar Alto, operated jointly by the Max-Planck Institut für Astronomie and the Instituto de Astrofísica de Andalucía (CSIC). This research has made use of the SIMBAD database, operated at ADC, Strasbourg, France.
